AUGER RECOMBINATION IN THE ELECTRON-HOLE DROPS IN Si AND Ge

ABSTRACT

Luminescence measurements on Si and Ge at temperatures of about 1.5 K are presented, which indicate that Auger recombination is the main recombination process inside the electron-hole drops (EHD) in both materials. In silicon a broad spectrum near 2 Eg due to Auger-excited hot electrons could be detected. From its intensity, an Auger lifetime can be derived which corresponds to the total EHD lifetime. In germanium, the evaluation of magnetooscillation in the luminescence intensity yields a quantum efficiency of only 25% and leads to the conclusion that 75% of the carriers inside the EHD recombine in Auger processes.

Recently, Auger recombination (AR) in the EHD was taken into consideration as important nonradiative process by several authors.1-3) While in germanium AR was only thought as important for the generation of free electrons and holes from the EHD,1) in Si and Si-Ge alloys AR was considered as possibly EHD-lifetime-determining.2,3) In the present paper luminescence measurements on Si and Ge are presented which can only be explained by the assumption that AR is the most important recombination process in the EHD in both materials.

For the case of silicon, the experiments were performed on highly pure samples cooled to about 2 K and excited by a pulsed GaAs laser (peak power 5 W, pulse length 1 μsec, duty factor 1%). Signal detection after a 0.75 m grating monochromator was carried out using an S 11 photomultiplier tube and special digital Boxcar technique.4) The near-2-Eg spectrum of silicon measured under these conditions is shown in Fig. 1. Besides the relatively intense two-electron transitions line at 2.27 eV,5,6) a weak, slightly structured spectrum
Fig. 1. The near-2-Eg luminescence spectrum of silicon. The relatively intense line at 2.27 eV is caused by two-electron band-to-band transitions.

at energies lower than 2 Eg arises. A better measurement of this region is shown in Fig. 2, the experimental points are indicated with their error bars. The process responsible for this spectrum is the following: 7) An electron is excited to a higher conduction band state by means of a phonon-assisted Auger-process in the EHD. During the relaxation from this state, there is the possibility for the electron to recombine radiatively with a condensed hole. This recombination causes the measured spectrum.

The main energy relaxation process for hot electrons in non-polar semiconductors - such as Si and Ge - well above the band edge is optical and acoustical deformation potential scattering. 8) For these two processes the relaxation rates have been calculated by Conwell. 9) Taking her formulas and the set of deformation potential constants from
Jørgensen et al.\textsuperscript{10} we have calculated the theoretically expected shape of the near-2-E_g spectrum originating from the described process. This is given by the full line in Fig. 2.

There have been 2 parameters fitted: One is the ratio of optical to acoustical relaxation rates which for a good fit could be chosen only 20\% from the calculated value (this may indicate the accuracy of the deformation potential calculation). The other is the absolute intensity of the spectrum, the fit of which, taking into account the radiative recombination coefficient\textsuperscript{11} and the reabsorption,\textsuperscript{12} yields the AR coefficient for the electron-electron-hole (e\textsubscript{eh}) process in the EHD in silicon. This value is found to be \( C_\text{e} = 1.5 \times 10^{-31} \text{ cm}^6 \text{ sec}^{-1} \), which is slightly enhanced compared to the high temperature value.\textsuperscript{13} The enhancement will be even more if one takes into account that the AR coefficient should increase with the temperature because of the participation of an acoustical phonon.
The value of $C_e$ results in an Auger lifetime for the $eeh$-process of $\tau_{eeh} \approx 500$ nsec; the $ehh$ process should be a little bit stronger in Si, so that the lifetime for both processes in AR is approximately 200 nsec. This is very close to the total lifetime of EHD in Si, which was found to be about 150 nsec.

On germanium, measurements of the magnetooscillations in the luminescence intensity have been performed. To the highly pure samples, which again were excited by a GaAs laser, a magnetic field in (100) direction could be applied in Faraday configuration. For signal detection a Ge photodiode (risetime $\approx 1 \mu$sec) and Boxcar technique was used.

The oscillations found in the luminescence intensity of the EHD-LA line of 709 meV are shown in Fig. 3. They change continuously in their amplitude with increasing delay time between excitation and signal detection, but the extrema positions remain fixed.

The oscillations are connected with oscillations of the carrier density inside the EHD according to the following formula:

$$\frac{\Delta i(H,t)}{i_0(t)} = \frac{\Delta n(H)}{n_0} \left(1 - t(B \cdot n_0 - 2 \cdot C \cdot n_0^2)\right)$$

(1)

where $i_0$, $n_0$ are intensity and carrier density at zero field, $\Delta i$ and $\Delta n$ are the oscillatory parts, $B$ and $C$ are the recombination coefficients for radiative recombination (RR) and AR, respectively, and $t$ is the time between excitation and signal detection. For the oscillations of the time integrated intensity $I(H)=I_0+\Delta I(H)=\int_{0}^{\infty} i(t) \, dt$ we can derive:

$$\frac{\Delta I(H)}{I_0} = \frac{\Delta n(H)}{n_0} \cdot \frac{A - C \cdot n_0^2}{A + B \cdot n_0 + C \cdot n_0^2}$$

(2)

where $A$ is the coefficient for impurity-induced nonradiative recombination.

From the curves in Fig. 3 those for $t = 0$ and for the integrated
intensity have been derived (Fig. 4). The curve for \( i(H,0) \) directly gives the variation of the equilibrium density inside the EHD as a function of the magnetic field (see eq. (1)). A comparison of the two curves gives the following condition for \( A \) and \( C \): \( A/C \cdot n_o^2 < 0.1 \). This indicates that in the EHD impurity induced nonradiative processes can be neglected compared to AR. Assuming \( A = 0 \), the quantum efficiency
Fig. 4. Oscillations of the luminescence intensity at $t = 0$ and of the time integrated luminescence intensity (calculated from the measurements in Fig. 3).

from the EHD can be derived to be $Q = 25\%$. This value is less by a factor of 2 and 3, respectively, than former estimations.$^{18,19)}$

With a total lifetime of $\tau = 36 \mu \text{sec},^{20)}$ the transition coefficients for RR and AR in the EHD can be calculated to be $B = 3 \times 10^{-14} \text{ cm}^3 \text{ sec}^{-1}$ and $C = 4 \times 10^{-31} \text{ cm}^6 \text{ sec}^{-1}$. The corresponding high temperature values are$^{21,11)} 1.1 \times 10^{-14} \text{ cm}^3 \text{ sec}^{-1}$ and$^{22)} 2 \times 10^{-31} \text{ cm}^6 \text{ sec}^{-1}$. From a comparison we can derive enhancement factors due to electron-hole correlation in the case of RR and to combined electron-electron or hole-hole and electron-hole correlation in the case of AR of $\rho_B = 3$ and $\rho_c \gtrsim 2$.

These values are very close to the theoretical ones which may be derived
from the values calculated by Vashishta et al.\textsuperscript{23)}

In Table 1 the results concerning the lifetime for RR and AR in the EHD are listed. For comparison also the lifetimes for two-

electron band-to-band transitions have been added, a fourth order process, which also has been found in both materials\textsuperscript{6,15)} but does not play an important role for the total lifetime. A comparison of the times shows the importance of Auger recombination in the EHD in both materials. Only in Ge radiative recombination may be nearly as strong as AR.

\textbf{ACKNOWLEDGEMENTS}

The author wishes to thank R. Conradt for valuable discussions and B.G. Zhurkin, A. L. Karuzskii, and B. M. Balter for help and discussion concerning the Ge experiments.
